Abstract:
Fishes are largely used for the assessment of aquatic environment quality and are accepted as bioindicators of environmental pollution. Studies of Hematology provide useful information on the effects of the external environment on the internal physiology of fish. This present study aims to evaluate the variation in blood parameters of *Clarias buthupogon* and *Heterobranchus longifilis*. Different hematological and biochemical indices like red blood corpuscles (RBC), white blood corpuscles (WBC), haemoglobin (Hb%), haematocrite (PCV) and erythrocyte indices like mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH), mean corpuscular haemoglobin concentration (MCHC), total Protein, glucose, cholesterol, albumin, chloride, hydrogen carbonate, potassium, sodium and calcium were determined using standard laboratory procedures. Generally, haematological indices were significantly (p<0.05) low in the dry season compared to rainy season. Plasma protein was low in the dry season (4.56 ± 1.45 g/dl) and slightly high during rainy season (11.12 ± 19.72 g/dl) and downstream A (3.73 ± 1.37 g/dl) to downstream B (11.94 ± 19.40 g/dl). Glucose level was high at downstream A (156 ± 12.12 g/dl) and in the dry season (150.94 ± 12.53 g/dl) while there was no significant correlation between the value of albumin (p<0.05) but there were significant correlations (p<0.05) for other biochemical indices for both sampling sites and seasons. Observation of blood parameters allows the most rapid detection of changes in fish after the exposure to xenobiotics. It can be concluded that hematological and biochemical parameters could be ranked as possible biomarkers of pollution.

Keywords: Toxic effects; Pollution; Bio-indicator; Aquatic; Asa river
**Introduction**

Influx of unwanted substances into our water bodies cause changes in the physical, chemical and biological characteristics of the aquatic system which lead to ecological imbalance. The industrial effluents contribute a lot to water pollution forming a threat to aquatic plants and animals (Ramona et al., 2001). A greater part of the pollutants exhibit biomagnification and bioaccumulation capabilities with a broad spectrum of impacts, and stresses on aquatic organisms (Censi et al., 2006). This leads to a steady decline in the aquatic flora and fauna, particularly fishes. Ogundiran et al. (2007) reported that the fishes are more susceptible to stress than many other animals because of their intimate dependence upon their surrounding environment. Aquatic organisms, like fish, accumulate pollutants directly from contaminated water and indirectly through the food chain (Riba et al., 2004 and Ashraf, 2005). Once the toxicant enters the body of the fish they may affect the organs leading to physiological and pathological disorders (Ogundiran et al., 2009).

The hematological index can be used effectively to monitoring the response of fishes to various toxicants reflecting the ecological status of the habitat and is a common method to determine the sub-lethal effects of the pollutant. Therefore, blood parameters are used as indicators for predicting the health whereabouts and toxicological symptoms of organisms, particularly fishes (Pimpao, 2007). Rios et al. (2002) reported that the hematological parameters in fish are influenced by factors such as sex, reproductive stage, age, size and health and the external factors such as seasonal dynamics, water temperature, environmental quality, food and stress. In another study, Elahee and Bhagwant (2007) reported that the fishes are more susceptible to stress than many other animals because of their intimate dependence upon their surrounding environment. Aquatic organisms, like fish, accumulate pollutants directly from contaminated water and indirectly through the food chain (Riba et al., 2004 and Ashraf, 2005). Once the toxicant enters the body of the fish they may affect the organs leading to physiological and pathological disorders (Ogundiran et al., 2009).

Haematological studies in fishes have assumed greater importance because these parameters were used as an efficient and sensitive index to monitor the physiological and pathological changes induced by natural or anthropogenic factors such as bacterial or fungal infection or pollution of water resources (Blaxhall, 1972). Blood parameters therefore considered as a useful tool in diagnosing the functional status of the body in response to various stressors (Houston and Carlile, 1997). The toxicants are stressors which are accumulated in the fish through the food chain or absorption through the general body surface and severely affect the life supporting system at molecular and biochemical levels. Pollutants generally produce relatively quick changes in the hematological characteristics of fish (Rizkalla et al., 1999). Therefore, the haematological studies are a potential tool to analyze the effect of toxicants on various target organs of fish in laboratory experiments and in field investigations (Kori Siakpere et al., 2005). In view of the above, this work aimed at evaluating the impact of water pollution on the hematological and biochemical indices of Clarias buthupogon and Heterobranchus longifilis collected from Asa River, Nigeria.

**Materials and Methods**

**Fish collection**

Live specimens of healthy Clarias buthupogon and Heterobranchus longifilis were collected from the downstream portion of the river with the help of local fishermen. Fishes of mixed sexes (smallest specimen caught for C. buthupogon had a total length of 11.4 cm, standard length of 8.6 cm and a total weight of 5.0 g while the biggest specimen caught had a total length of 48.5 cm, standard length of 43.2 cm and a total weight of 50 g. For H. longifilis, the smallest specimen caught had a total length of 23.4 cm, standard length of 20.0 cm and a total weight of 80g, and the biggest specimen had a total length of 65.3 cm, standard length of 62.8 cm and a total weight of 2,700 g) were collected and the blood of fishes were collected immediately on site from the caudal peduncle (KocabatmA and Ekngen, 1982) in EDTA (ethylene diamine tetraacetate) coated tubes during the morning hours at a fixed time to avoid diurnal variation in the blood parameters for further analysis. The total erythrocytes count and leucocytes count were enumerated in an improved Neubauer hematocytometer using Hayem’s diluting fluid and Turk’s fluid, respectively in light microscope. Hemoglobin (Hb) concentration was measured by Sahli method. The microhematocrit method was used to determine the hematocrit (PCV). The hematological indices: such as mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) were calculated from the equation given by the Dacie and Lewis (2001). The biochemical analysis was done by simply centrifuge blood sample at 4000 rpm for 20 min (centrifuge; Universal 320 R (Hettich Zentrifugen)) to separate the plasma and analyzed. The separated serum was then analysed for total protein (TP) and blood enzymes such as Lactate dehydrogenase (LD), Alkaline phosphatase (ALP), Alkaline transaminase (ALT) and Aspartate transaminase (AST). An automatic blood enzyme analyzer (Hitachi 704) was used for the following determinations: Total protein (TP, g l$^{-1}$), Lactate dehydrogenase (LD, µkat l$^{-1}$), Alkaline phosphatase (ALP, µkat l$^{-1}$), Alkaline transaminase (ALT, µkat l$^{-1}$) and Aspartate transaminase (AST, µkat l$^{-1}$). The apparatus is based upon dry chemical technology and colorimetric reaction. Kits obtained PLIV Alachema and DIALAB, were used for the determination of all serum indices. Na, K, Ca, P, CI were measured by kits (Lot numbers of kits; E485, F133, F108, E485 and E389, respectively (purchased Thermo SCIENTIFIC) using Konelab Prime 601. The hematological and biochemical parameters are expressed in international units (SI).

**Results and Discussion**

The results of haematological parameters are presented in Figures 1-4. The results revealed that the PCV, Hb and RBC counts in fishes showed significantly higher value during rainy season.
as compared to dry season. A highly significant enhancement in W.B.C. was also observed in dry season as compared to rainy season. The results of red cell indices viz., MCV, MCH and MCHC revealed significant increase (p<0.001) in rainy season as compared to dry season. The results of ANOVA revealed a significant seasonal effect on RBC (p<0.05), WBC (p<0.001), Hb (p<0.01), PCV (p<0.001). The results of the red cell indices showed a highly significant (p<0.001) seasonal effect in MCV and MCHC. Studies have shown that the seasonal changes affect the water quality and the fishes being aquatic organism, its physiology is greatly affected by the aquatic environment (water) which internals influenced by the seasonal changes. Blood cell responses are important indicators of changes in the internal and/or external environment of animals. Water quality cans thus be regarded as one of the major factors responsible for individual variations in fish haematology. Figures 5-8 revealed the biochemical responses of the two-sampled fish to the polluting water body. Blood plasma was analyzed for various biochemical parameters viz; total Protein, glucose, cholesterol, albumin, chloride, hydrogen carbonate, potassium, sodium and calcium. Significant change was observed in the biochemical parameters in the blood of the two fish species examined in this present study. There was a decline in the blood plasma protein content during the dry season and at the upstream sit of the river. The cholesterol level likewise decreased and increased in the same manner as the plasma protein. Blood glucose content decreased markedly from dry to rainy seasons and the highly polluted upstream recorded high value compared to low value recorded for the downstream. Potassium, sodium, calcium, albumin, chloride and hydrogen carbonate increased from dry to rainy season and was equally found to increase in values from upstream to downstream. In this study blood serum components (LDH, ALP, ALT) analysis revealed obvious significant differences (P<0.05), and their value decrease from upstream to downstream and from rainy to dry season. Haematological indices are very important parameters used in the evaluation of fish physiological status (Ogundiran, 2007; Adewoye, 2010 and Yekeen and Fawole, 2011). A decrease in
the value of RBC (Erythrocyte count) and in the percentages of PCV (Haematocrit) in this study indicated a worsen state of an organism’s condition and its developing anemia. Decrease in the concentration of haemoglobin in the blood, which may be linked to the effects of toxic metals on blood, as well as decrease in oxygen may also indicate anemia or confirm negative changes occurring in fish species used in this work. An increase in the WBC (Leucocytes count) is mostly observed during the initial stage of stress reaction when fish tries to restore disturbed homeostasis, however later, a decrease of leucocytes count can be observed, which shows the weakening of immune system on the basis of haematological studies, it would be possible to forecast the physiological state of fish in natural water bodies (Adeyemo et al., 2003 and Ogundiran et al., 2007). The count of RBC was quite a stable index and the fish body attempt to maintain this count within the limits of certain physiological standards using various physiological mechanisms of compensation. Haemoglobin concentration reflects the supply of an organism with oxygen and the organism itself attempts to maintain the oxygen level as much stable as possible. Therefore, all hematological indices can be secondary responses of an organism to pollutant/irritants or changing environment.

Among analyzed haematological indices, RBC, HB, PCV values were found to be lower in the dry season and slightly high in the rainy season and, the same trend was also observed in the upstream and downstream sites of the river; this may be due to an inhibited RBC production in the haematopoetic organs and or may be linked to impaired haemoglobin synthesis. Ambient toxicant might have been responsible for disintegration of RBC cells, which in turn have caused reduction of haemoglobin and PCV (haematocrit) count. This confirmed an anemic condition in the blood sample of the two examined fish species; Anemia of this magnitude is characterized by the reduction in the RBC count, PVC percentage and haemoglobin contents which have also been reported by several workers after heavy metal exposure (Adyemo et al., 2003 and Ogundiran, et al., 2007). Existing data

Note: EPU- Endopentosanase units.
on the effects of pollutants on RBC indicated that pollutants like
insecticide and industrial effluents have affinity for the blood
stream, which produced a number of abnormalities in the blood
(Adewoye, 2010 and Yekeen and Fawole, 2011). Pollutants
like insecticides have the capacity to penetrate into the RBC
(Yekeen and Fawole, 2011), this was reported to have induced the
formation of anti-erythrocyte antibodies. The reasons for decrease
in erythrocytes from the blood may be extravasations, a plastic
anaemia or immunohaemolytic anaemia.

Slightly increased level of Mean Cell Volume (MCV),
Mean Cell Haemoglobin (MCH) and Mean Cell Haemoglobin
Concentration (MCHC) value was evident in this work and
this is an indication that anaemia produced, is of macrocytic
cytochromic type. MCHC is a good indicator of red blood cell
swelling (Wepener et al., 1992 a & b). The MCHC is not in any
way influenced by the blood volume or by the number of cells
in the blood but can be interpreted incorrectly only when new
cells with different haemoglobin concentrations, are released into
blood circulation (Adewoye, 2010). The significant decrease in
the value of MCHC at upstream and in the rainy season may probably
be attributed to red blood cell swelling. In another instance, a
significant decline in the values of MCH and MCHC have also been
reported by kahak and Hafeez (1996) in fish, Cyprinid Watsoni
exposed to extensively used agriculture pesticides malathion.
A drop in the MCHC value was also reported by Qureshi et al.,
(1993) and Omorogie et al., (1994) when fish are exposed to polluted environment under
laboratory conditions; the anaemic effects reported here could be
due to destruction of erythrocytes or the inhibition of erythrocyte
production (Omorogie et al., 1994) and haemodilution (Sampath
et al., 1993).

Changes in the WBC and RBC in fish have been reported to be
a strong indicator of stress due to the presence of toxicants in the
aquatic environment. WBC count increased at upstream location
of Asa River compared to the downstream and this may be an
indication of high pollution load recorded upstream. Also, during
the dry season, WBC was noticed to be very high compared to
the rainy season when the volume of water became high; this is
perhaps, a typical defensive response of the fish against a high toxic
invasion. Both leucopenia and conversely leukocytosis (increased
number of WBC) have been submitted in fish populations exposed
to heavy metals (Ogundiran et al., 2001). In this present study, the
percentage of PCV was lower for upstream and dry season where
pollution load was high. Generally, WBC abundance provides an
indication of fish health and a high WBC count may indicate a
sub-clinical infection.

Generally, blood is one of the most sensitive indicators of much
metabolic disorderliness occurring in the body, therefore, blood
test play a key role in the easy and rapid diagnosis of ailments
occurring in the animal body. In the present investigation, plasma
protein level decreased in both species examined from dry season
to rainy season, and from upstream to downstream, when and
where the pollution index were noticed to be high respectively.
The decreased protein level is an indication of hyper protein
anaemia; which can be correlated with the possible inhibition
of protein synthesis occurring in the body. However, nutritional
imbalances, infection due to high chemical pollutants noticed
upstream and in the dry season, kidney damage or inanition (i.e.
condition of exhaustion caused by a lack of nutrients in the blood)
due to pollution could be the other possible reasons. Reduction
in the value of protein could also be due to inhibition of RNA
synthesis or proteolytic activities. When the energy demand of
the body is very light such that energy derived from gluconeogenesis
and glycolysis are not enough, more energy may be obtained
through synthesis of glucose from non-carbohydrate sources
including protein (Glucogenesis). This will lead to a reduction
in the level of protein which may eventually lead to emaciation in
exposed fish species. Such reduction in protein due to exposure
to toxicant had been reported in fishes (Maruthanayagam and
Shormila, 2004). Low plasma protein in effluent exposed fish
species was also recorded in a similar study and it was correlated
to possible nutritional imbalance, infections disease, kidney
damage or lack of nutrients in the blood, due to the polluted nature
of the environment. In another study, the toxic effects of heavy
metals like copper and zinc, and their mixture were studied on
some selected blood biochemical parameters in common carp,
Cyprinus carpio at sub lethal level over a period of 30 days,
and it was submitted that, total serum protein were decreased
significantly (Dhanapakian and Ramasamy, 2001). Similarly,
sunfish populations (Lepomis spp.) inhabiting selenium-laden coal
in the effluent polluted water body showed a significantly lower
plasma protein levels and were correlated with possible nutritional
stress and disease (Lohner et al., 2001c). However, Dethloff et al.,
(2001) reported wild rainbow trout from a creek receiving run-
off from a copper mine with total protein remained unaffected
in another investigation, the effects of petroleum hydrocarbons
on two marine fish species winter flounder, Pseudopleuronectes
americanus and Atlantic cod, Gadus morhua was carried out and a
significant decreased in total protein were reported (Kham, 1987
which is in conformity with the findings in the present study. Also,
Sheriff et al., (2001) submitted a significant increase in total blood
protein after feeding copper to Javanese Carp, Puntius gonionotus
(Bleeker). Van vuren et al., (1994) reported an increase in blood
protein (hyperproteinaemia) in fish, Clarias gariepinus exposed
to copper and this was not in agreement with the observation
recorded in this present study. Meanwhile Indian major carp,
Labeo rohita exposed to pesticides, cypermethrin while glucose
level was found at an elevated level (sheriff et al., 2001).

Glucose is one of the highly sensitive features of stress nature
of an organism; its high concentration in blood plasma of the two
fish species caught from upstream and in the dry season in this
study, indicated that the fish is in stress and it is intensively using
its energy reserves (i.e. glycogen in liver and muscles). Meanwhile,
a decrease in concentration observed indicates the exhaustion of
energy (glycogen) resources and subsequently, the worsening of an organism status. A decrease in glucose in blood plasma was observed in a long-term exposure to heavy metals (Vosyliene, 1999a, b). The above submission can better support the results in this present investigation and an increase in the glucose level in the blood plasma of the two fish species, both at upstream and dry season, conformed to the general studies worldwide. Increased glucose level in fish species at upstream and in the dry season reflected hyperglycemia, while decrease in the downstream and in the rainy season, reflected hypoglycemia and these may be attributed to high and low level of pollution at upstream, dry season and downstream and rainy season respectively. Generally, both the conditions of different response of plasma glucose confirmed the presence of ailments in the fish species, a condition that may be the resultant effects of pollution. Hyperglycemic conditions developed either due to increased glycolysis or decrease in glucose utilization by the cell, which means the inhibition of glycolysis. It has been suggested that the mechanism behind the induction of hyperglycemia is the activation of sympathetic nervous system, which resulted in the release of adrenaline from adrenal medulla.

Adrenaline then stimulated the pituitary to produce greater amount of ACTH which in turn activated the adrenal cortex to secrete more glucoorticoid hormones which are responsible for increased glucose production from liver with the consequent release into the blood (Sreenivasan, and Moorthy, 2011). Fox and Virgo (1986a) concluded that Dieldrin affects hyperglycemia by stimulating the lateral hypothalamus, thus increasing the cholinergic and alpha-1-adrenergic stimulation of the pancreas. This would result in an increased release of glucagon and decreased secretion of insulin with the development of hyperglycemia (Maruthanayagam and Shormila, 2004). The different variations of plasma glucose recorded across the sample locations and the two seasons of the year. The decrease in glucose content observed in this work most especially at the downstream portion of the river and during the rainy season of the year may probably be related to increased glucose utilization required for the induction of liver enzymes and microsomal protein under fair environmental stability. Similarly, in a laboratory study where rainbow trout, Oncorhynchus mykiss exposed to sublethal concentrations of Cu (14 µg/l) and Zinc (57 and 81 µg/l) showed an increase in plasma glucose (Dethloff et al., 1999). Also, common Carp, Cyprinus Carpio treated with copper sulphate (CuSO4), parquat and methidalthion exhibited increased blood glucose level (Aszlalos et al., 1990). In another study, the effects of heavy metal mixtures like Cu and Zn were studied on some blood biochemical parameters in fish at sublethal level over the period of 30 days, serum glucose were decreased significantly (Dhanapakian and Ramasamy, 2001). Van Vuren et al., (1994) also reported an increase in blood glucose (hyperglycemia) in fish, Clarias gariepinus exposed to Cu, after 2-hours of exposure, the count of glucose increased in the blood of Carp (Nemscok, et al., 1985). An increase in glucose count was observed only after acute exposure to copper (Vosyliene, 1996b). An increase in glucose concentration was also observed in various fish species after their 15-day exposure to 10mg/l of hexavalent chromium Exposure to water from lower Rhine River induced a stress response by increasing glucose level in Rainbow trout (Nolan et al., 2003).

Like total protein, cholesterol also decreased significantly in both the grossly polluted location and in the dry season when polluted load was high and the resultant effects is termed hypcholesterolaemia. High cholesterol in the serum of the two fish species showed high lipoprotein content in the blood. Changes in blood cholesterol level are related to changes caused by the action of chemical pollutants in the river in the permeability of hepatic cells (Yousef et al., 2003). Accumulation of pollutants in the liver is reported to disrupt lipid metabolism and increase serum cholesterol level (Yousef et al., 2003; Kalender et al., 2005). The decrease in cholesterol level recorded in the present investigation may be linked to the lack or low availability of starting material acetyl-CoA for cholesterol synthesis in the absence of glucose utilization and dependence of body on alternate energy source (gluconeogenesis). Considerably, variation was found in serum cholesterol and protein contents after indiscriminate feeding to a freshwater fish, Clarias batrachus. Folmar (1993) noted significantly lower serum cholesterol and was thought to be associated with the chronic stress of being in an environment contaminated with chlorinated pesticides, PCBs and heavy metals. There was no significant difference in the value of albumin while there were significant correlations for chloride, potassium, sodium, calcium and hydrogen carbonate for both sampling sites and the two seasons of the year.

Tables 1 and 2 showed the serum activities of the two bioindicators species studied in this work and an increased activity of AST, ALT, ALP and LDH in the plasma of C. Bathupogon and H. longifilis indicate that long-term exposure to chemical pollutant causes tissue damage in fish and this has also been reported in O. mykiss and Channa punctatus, exposed to diazinon and monocrotophos respectively (Banaee et al., 2011). The plasma activity of this serum indices helps to determine tissue damage in

fish and this study has revealed that water pollution has a direct impact on the serum activities of the blood.

Conclusively, the toxic effects of water pollution in fish have been demonstrated in the present study and it was established that pollutants in water could be moderately toxic to aquatic faunas. Therefore, it was proven that the use of the selected biochemical markers and chemical analyses has been a suitable tool to monitor the level of contamination of aquatic environment.
